## PRIORITY DOCUMENT

SUBMITTED OR TRANSMITTED IN  
COMPLIANCE WITH RULE 17.1(a) OR (b)

I, the undersigned, being an officer duly authorised in accordance with Section 74(1) and (4) of the Deregulation & Contracting Out Act 1994, to sign and issue certificates on behalf of the Comptroller-General, hereby certify that annexed hereto is a true copy of the documents as originally filed in connection with the patent application identified therein.

I also certify that the attached copy of the request for grant of a Patent (Form 1/77) bears an amendment, effected by this office, following a request by the applicant and agreed to by the Comptroller-General.

In accordance with the Patents (Companies Re-registration) Rules 1982, if a company named in this certificate and any accompanying documents has re-registered under the Companies Act 1980 with the same name as that with which it was registered immediately before re-registration save for the substitution as, or inclusion as, the last part of the name of the words "public limited company" or their equivalents in Welsh, references to the name of the company in this certificate and any accompanying documents shall be treated as references to the name with which it is so re-registered.

In accordance with the rules, the words "public limited company" may be replaced by p.l.c., plc, P.L.C. or PLC.

Re-registration under the Companies Act does not constitute a new legal entity but merely subjects the company to certain additional company law rules.

## Warning

After an application for a patent has been filed, the Comptroller of the Patent Office will consider whether publication or communication of the invention should be prohibited or restricted under Section 22 of the Patents Act 1977. You will be informed if it is necessary to prohibit or restrict your invention in this way. Furthermore, if you live in the United Kingdom, Section 23 of the Patents Act 1977 stops you from applying for a patent abroad without first getting written permission from the Patent Office unless an application has been filed at least 6 weeks beforehand in the United Kingdom for a patent for the same invention and either no direction prohibiting publication or communication has been given, or any such direction has been revoked.

## Notes

- If you need help to fill in this form or you have any questions, please contact the Patent Office on 08459 500505.
- Write your answers in capital letters using black ink or you may type them.
- If there is not enough space for all the relevant details on any part of this form, please continue on a separate sheet of paper and write "see continuation sheet" in the relevant part(s). Any continuation sheet should be attached to this form.
- If you have answered 'Yes' Patents Form 7/77 will need to be filed.
- Once you have filled in the form you must remember to sign and date it.
- For details of the fee and ways to pay please contact the Patent Office.

PACKET ROUTING

The present invention relates to a packet router, a network and a method of routing a packet.

5

In this document, unless the context indicates the contrary, the term "packet" includes data packets of any type, and specifically includes ATM cells.

10

Routers containing multistage switches such as Banyan or Clos networks are known in the art. One problem with switches for circuit or packet switching is internal blocking. Internal blocking is a condition where it is not possible to find a free path from source to

15

destination. Multistage switches such as the Clos 3-stage architecture which can be made to be strictly non-blocking in a circuit switching context will, with the same architecture, block in the packet switching context.

20

However by increasing their dimensions, Clos and other multistage architectures can be made to become substantially non-blocking to the point where packet loss is low enough to be acceptable.

25

To accomplish very high data rates, for example for Internet traffic of the multi-terabit order, there has been proposed a hybrid electro-optical switch with optical fan-out, optical fan-in and optical shutters acting as the spatial path selection means. Optical sources are provided by vertical cavity surface emitting lasers

30

(VCSEL) and silicon photodetectors provide the optical source terminations. For large switches it is

advantageous to use free-space connections within the switch to provide the paths..

5        So as to be able to buffer or queue data, it is  
necessary to provide storage. A simple switch may use a  
conventional dual-ported RAM common to the packet inputs,  
with writing to memory of the data from each input in  
sequence using a demultiplexer or distributor. However,  
this is predicated upon sufficient time being available to  
10    write data from all inputs before new inputs have arrived.  
When the number of writes of data multiplied by the  
average access time per write exceeds the total access  
time of the memory, this technique can no longer be used  
without loss of data.

15

Clearly a major source of the problem lies in the  
memory write bus at the output of the demultiplexer, as  
this must be shared among all of the incoming packet  
sources. To avoid this problem, it would be possible to  
20    provide  $n$  memories for  $n$  input ports, but that would be  
prohibitively expensive, and complex. Instead, the inputs  
can be grouped into so-called "sectors" with, say,  $m$   
inputs per sectors and each sector sharing access to a  
memory dedicated to the sector. Outputs are grouped in  
25    the same way.

Then, when a packet is received at an input and  
having a packet header indicating a desired output node,  
the packet data are transferred from the input sector  
30    containing the input to the output group containing the  
desired output node. The output module containing the

output group then routes the packet data to the desired output.

5 This technique also allows the number of connections between the sectors to be less than the  $n \times n$  connections needed to provide full connectivity between  $n$  inputs and  $n$  outputs.

10 The number of inputs per sector may be chosen on a memory bandwidth basis. However, other factors may come in such as choosing  $m$  to divide into  $n$  to produce an integer and preferably a power of two, e.g. 16 or 256.

15 Queuing has the further disadvantage of introducing delays into the transmission.

Networks are often categorised into three types:

LANs --- Local Area Networks

MANs --- Metropolitan Area Networks

20 WANs --- Wide Area Networks

The LAN is a very common type of data network. A LAN:

- \* is local (i.e. one building or group of buildings.
- \* is controlled by one administrative authority.
- 25 \* assumes other users of the LAN are trusted.

A WAN is usually a network covering a large geographical area, using communications circuits to connect the intermediate nodes. The communications  
30 circuits of most WANs are owned by or leased from telephone companies or other communications carriers. The characteristics of WANs lead to an emphasis on efficiency

of communications techniques. Controlling the volume of traffic and avoiding excessive delays is important.

The MAN has three important characteristics:

- 5        1. The network size falls intermediate between LANs and WANs. A MAN typically covers an area of between 5 and 50 km diameter. Many MANs cover an area the size of a city, although in some cases MANs may be as small as a group of buildings or as large as the North of Scotland.
- 10       2. A MAN (like a WAN) is not generally owned by a single organisation. The MAN, its communications links and equipment are generally owned by either a consortium of users or by a single network provider who sells the service to the users.
- 15       3. A MAN often contains a number of packet routers and acts as a high speed network to allow sharing of regional resources (similar to a large LAN). It is also frequently used to provide a shared connection to other networks using a link to a WAN.

20

Another important characteristic of a MAN is that it may use network-specific addressing for packet transmission within the MAN rather than relying on the global IP address. Typically the MAN contains routing

---

25 tables under control of a network controller to determine how a packet should pass between two nodes of the MAN. These routing tables are likely to be variable according to traffic conditions. Local addressing is employed as it is shorter than full IP addressing.

30

Other types of network have characteristics crossing the above bounds. For example, wholly owned networks

(c.f. LANs) may cover large geographical areas (c.f. WANs).

Among the problems of prior art networks and routers  
5 are those of control and time delay. It is desirable to  
have local control that allows operation of a router to  
take place without the need for real-time intervention by  
the network controller. It is also desirable to provide  
architectures in which the number of queues can be kept  
10 low to avoid adding delays. As queue management presents  
an appreciable control overhead, it is also desirable to  
reduce the number of queues to enable simpler control  
systems.

15 According to a first aspect of the invention there is  
provided a packet router comprising an input stage, an  
output stage and a coupling stage for coupling the input  
and output stages,

the input stage having plural input devices each for  
20 receiving packets having packet data comprising packet  
destination data, each input device having at least one  
output element;

the output stage having plural output devices  
defining plural router output nodes, each output device  
25 having at least one input element;

the coupling stage providing paths between said  
output elements of the input devices and said input  
elements of the output devices;

wherein each input device has circuitry arranged to  
30 respond to packet destination data of a packet received by  
said input device for adding, to the packet data of the

packet, information indicative of a router output node at which the packet is to be output;

wherein the router further comprises a control device connected to said input stage and to said coupling stage  
5 for causing packets to be output to said coupling stage in dependence on said information;

wherein each output device has circuitry for removing said information prior to output of packets; and

wherein the router further comprises a connecting  
10 device arranged to receive said signals from paths of the coupling stage and to transfer said signals to a further said output device disposed remote from said input stage.

In the context of a MAN, the router input devices may  
15 be in one building for example, with some output devices in the same building and the further output device in another building. The links between the inputs and outputs may then be controlled by the router control device. This means that local control can provide good  
20 use of the links, and may reduce the number of connections between the buildings by comparison to a conventional network.

---

The provision of an output device which is remote  
25 from the input stage allows flexibility in use of the connections between the input stage and output devices. In a conventional router, connections from the router to each destination device will need to be dimensioned to accept the largest expected traffic, if delays are not to  
30 occur. If each of say four destination devices have a peak traffic flow which requires two lines from the router output, then eight such lines will be required. With the

present router the output device may be physically close to the destination devices. A connecting device with only, for example, six paths may suffice provided high traffic conditions do not occur to all the destinations  
5 simultaneously.

In one embodiment said coupling stage is arranged to vary the paths between the input stage and the output stage, and said control device is arranged to cause  
10 packets to issue from the input stage when a desired path is provided.

In this embodiment the coupling stage may for example automatically cycle between different path combinations  
15 without being fully controlled by the control device. Alternatively the network controller controls the coupling stage to cause reconfiguration when the traffic flow varies at the macro level, for example when a change in the statistics of the traffic occurs. In both these  
20 cases, and in other cases where the coupling device does not respond directly to the needs of individual packets, the control device only has to release data when an appropriate path is provided.

25 In another embodiment said control device is arranged to control the coupling stage to set up a desired path from the input stage to the output stage and to cause packets to issue from the input stage for the desired path.

30

In this embodiment, the control device controls the coupling stage either in dependence on the presence of

particular individual packets, or in dependence upon a sensed queue condition or in other ways so as to set particular paths through the coupling stage. Once the desired paths are achieved, packets then issue for them.

5

In some embodiments the coupling stage is arranged to provide at least one fixed path.

10 The computing overhead of the control device can be reduced by providing one or more fixed paths through the router. In such embodiments, the controlled paths through the coupling stage may be used to smooth out traffic flows.

15 Preferably the input devices comprise segmenting circuitry arranged to divide received packets into segments of common length prior to application to said coupling stage, wherein each segment includes the said information and the output devices comprise de-segmenting  
20 circuitry arranged to assemble segments received from said coupling stage into packets.

By segmenting the packets there are three major advantages. One is the ability of the router to cope with  
25 packets or arbitrary length, the second is to enable the efficiency of the device to be high and the third is to match the segment length to the width (word length) of the internal memory such as a standard value of 128 bits.

30 In this respect, if the segments are similar in length to the minimum packet or cell size there will be no need to transmit large numbers of stuffing bits, such as

would be required if the window for packet transmission were equal to the maximum packet length.

In preferred embodiments the input devices have  
5 optical output elements, the output devices have optical input elements and the coupling stage is arranged to provide free-space optical paths between said optical output elements and optical input elements.

10 The use of free-space optical paths provides a less expensive and more flexible technique than would be required by optical fibres. The ability to include simple controlled gating devices in the optical paths means a substantial power reduction by comparison with similar  
15 electrical devices. Cross-talk is also less than would be the case in electrical embodiments.

Advantageously the connecting device comprises a passive optical network.

20

Advantageously again the input stage has a plurality of inputs capable of carrying a first plurality of packets to said router in a given time period, and the coupling stage is capable of providing said paths between said  
25 output elements of the input devices and said input elements of the output devices, wherein said paths are arranged to be able to carry more than said first plurality of packets in said given time.

30 Conveniently the number of spatially separate paths provided by said coupling stage is greater than the number of inputs to said input stage.

According to a second aspect of the invention there is provided a network comprising a packet router wherein each input device comprises storage for holding queues of packet data prior to issue to said coupling stage, and  
5 each output device has storage for queues of packet data received from the coupling stage, and further comprising at least one second packet router having a second router input stage, a second router output stage and a second  
10 router coupling stage for coupling the second router input and output stages, wherein the second router input stage has plural input devices each for receiving packets having packet data comprising packet destination data, each second router input device having at least one output  
15 element and storage for holding queues of packet data prior to issue to said second router coupling stage, wherein the second router output stage has plural output devices defining plural output nodes, each output device having at least one input element, wherein the second  
20 router coupling stage is arranged to provide paths between said output elements of the input devices and said input elements of the output devices, and wherein at least one of the input devices of the second router input stage is provided by said further said output device of said packet  
25 router disposed remote from said input stage of said first packet router, each said queue of packet data received from the coupling stage of the first packet router forming a queue of packet data prior to issue to said second router coupling stage.

30

In this aspect, the invention allows for one router to have a remote output which is the input to another

router. Apart from allowing flexibility of utilisation of the paths, this also results in queue number reduction.

It is possible to do this because the claimed architecture allows for immediate control to be needed only in the

5 input and coupling stages, with there being no requirement for the output stage or output device to communicate with the input stage or coupling stage at the packet level.

The network contains a plurality of routers. Of this plurality the first router is connected to only a second  
10 router of the type defined in one embodiment. However, in other embodiments, the first router may be connected to any number of second routers up to a number equal to the number of segments in the first router.

15 According to a third aspect of the invention there is provided a network comprising a first and at least one second packet router, each packet router comprising an input stage having plural input devices, an output stage having plural output devices and a coupling stage for  
20 providing paths between said input devices and said output devices; each input device having storage for holding queues of packet data prior to issue to said coupling stage, each output device having storage for queues of packet data received from the coupling stage; wherein at  
25 least one of the input devices of the second packet router is provided by an output device of said first packet router such that each said queue of packet data received from the coupling stage of the first packet router forms a queue of packet data prior to issue to said coupling stage  
30 of said second router.

Again, the network contains a plurality of routers. Of this plurality the first router is connected to only a second router of the type defined in one embodiment. However, in other embodiments, the first router may be  
5 connected to any number of second routers up to a number equal to the number of segments in the first router.

Preferably each packet router has a respective control device connected to its input stage and to its  
10 coupling stage for outputting packets to said coupling stage in dependence on routing information carried by packets.

Advantageously the coupling stage of at least the  
15 first packet router is arranged to optically couple the input stage of the first packet router to the output stage of the first router.

Advantageously the said coupling stage is arranged to  
20 provide free-space connections.

According to a fourth aspect of the invention there is provided a method of routing packets using a packet  
router comprising an input stage, plural output devices  
25 and a coupling stage for coupling the input stage and output devices, wherein at least one of the output devices is spatially remote from the coupling stage;

the method comprising:-

in said input stage, examining packet destination  
30 data of a packet received by said input stage and in response thereto

adding, to the packet, router information indicative of a router output node of said at least one of said output devices, at which the packet is to be output to provide enhanced packet data;

5 in dependence on said router information, determining whether a path is available from an input of said coupling stage to an output connected to said at least one output device;

outputting said enhanced packet data to said input of  
10 said coupling stage, whereby the enhanced packet data is carried to an output of said coupling stage for said at least one output device having the said router node;

receiving the enhanced packet data from said coupling stage output and transferring the packet data over a link  
15 to said at least one output device;

receiving said enhanced packet data in the said output device;

removing said router information; and

outputting said packet at said router output node.

20

According to a fifth aspect of the invention there is provided a method of routing packets using a router comprising an input stage having plural output elements, plural output devices each having plural input elements,  
25 the plural output devices each having a plurality of output nodes, said output nodes together defining the output nodes of said router, and a coupling stage for coupling the plural output elements of the input stage to plural coupling stage outputs, wherein at least one output  
30 device is spatially remote from the coupling stage and the router further comprises a link between predetermined

outputs of said coupling stage and the plural inputs of  
said at least one output device;

the method comprising:-

receiving respective packets at each of plural inputs  
5 of said input stage;

in response to packet destination data of said  
packets, adding to each packet respective router node  
information indicative of a router output node at which  
the said packet is to be output, thereby to form enhanced  
10 packet data comprising said packet data and said router  
node information;

storing said enhanced packet data for each packet in  
a common input memory;

in dependence on said router node information  
15 indicative of an output node in said at least one output  
device, determining an available path through said  
coupling stage from an output element of said input stage  
to one of said predetermined outputs of said coupling  
stage;

20 outputting said enhanced packet data from said common  
input memory to said output element, whereby the enhanced  
packet data is carried to one of said predetermined  
outputs of said coupling stage;

---

transferring the enhanced packet data over said link  
25 to one of said plural inputs of said at least one output  
device;

receiving said enhanced packet data at the said  
output device;

removing said router node information indicative of  
30 said output node to form packet data;

storing said packet data in a memory common to the input elements of said output device and to the output nodes of said output device; and

outputting a packet at said router output node from  
5 said memory.

Advantageously the method comprises varying paths provided by said coupling stage between the input stage and the output stage, and causing packets to issue from  
10 the input stage when a desired path is provided.

Preferably the varying step comprises providing a sequence of path combinations, and selecting between said path combinations on a timed basis.

15

In one embodiment said varying step comprises providing a sequence of path combinations, and selecting between said path combinations in accordance with a statistical analysis of traffic in said router.

20

In another embodiment the method comprises controlling the coupling stage to set up a desired path from the input stage to the output stage and issuing packets from the input stage to the desired path.

25

In some embodiments, the coupling stage is arranged to provide at least one fixed path.

Preferably the method comprises dividing received  
30 packets into segments of common length prior to application to said coupling stage, and adding the said

information to each segment; and assembling segments received from said coupling stage into packets.

Advantageously the method comprises coupling between  
5 the input stage and the output devices by free-space optical paths.

Conveniently the transferring step is carried out using a passive optical network.

10

Advantageously the method comprises carrying packet data across said coupling stage faster than said packet data is received at said input stage.

15

Conveniently the method comprises providing a number of spatially separate paths in said coupling stage wherein said number is greater than a number of inputs to said input stage.

20

Preferably the method comprises:

holding queues of packet data prior to issue to said coupling stage,

holding queues of packet data received from the coupling stage,

---

25

locating at least one of said queues of packet data received from the coupling stage at an input of a second router having a second router coupling stage, said second router holding queues of packet data prior to issue to said second router coupling stage, and using said at least  
30 one of said queues as a said queue of packet data prior to issue to said second router coupling stage.

An embodiment of the invention will now be described with reference to the accompanying drawings in which:-

Figure 1 shows a block schematic diagram of a packet router useful in understanding the present invention;

5        Figure 2 shows a more detailed schematic diagram of the input side of Figure 1;

Figure 3 shows a more detailed schematic diagram of the output side of Figure 1;

Figure 4 shows a schematic diagram of a router, for  
10 explaining the concept of 'speed-up';

Figure 5 shows a schematic diagram of a router, for explaining the concept of sectorisation;

Figure 6 shows a schematic diagram of a further example of a packet router;

15        Figure 7 shows a high-level block diagram of control of one sector of the input stage to the core switch of a sectorised router;

Figure 8 shows a block diagram of an example of a re-timing buffer;

20        Figure 9 shows an example of an implementation of Figure 7;

Figure 10 shows a block schematic diagram of an embodiment of the output stage electronics;

Figure 11 shows a block schematic diagram of a  
25 Metropolitan Area Network; and,

Figure 12 shows a block schematic diagram of a router in accordance with the invention in a MAN.

In the various figures, like reference numbers refer  
30 to like parts.

Referring to Figure 1 an exemplary packet router useable in a MAN has three stages 1, 10 and 15. The first stage 1 receives signals from four input lines 2-5 of the MAN, carrying packet data. In the embodiment shown in  
5 Figure 1 the first stage 1 has four output lines 6-9 which form the input lines to the second stage 10, hereinafter referred to as the core switch. The core switch has four output lines 11-14 which form the inputs to the third stage 15, the output stage, which in turn has four output  
10 lines 16-19. A control unit 20 is local to the router, in the sense that its connections to the router allow it to respond to router conditions in real-time. The control device has connections 21, 22 and 23 connected to respectively the first, second and third stages of the  
15 router.

The functions of the first stage 1 include sorting packet data according to the output port of the router to which the packet is to be routed, and queuing the sorted  
20 input packet data in local buffers until the core switch 10 is able to carry them to the output stage 15. The core switch has the function of delivering information provided at each one of the four core switch inputs to core switch  
outputs. The output stage has the main function of  
25 holding data received from the core switch for output.

Each of the input packets includes network header information which indicates the destination network address of the packet, and which determines which of the  
30 router output lines 16-19 the packet is to be routed to. The router operates using data of a fixed number of bits, and input packets with more bits than the fixed number are

segmented by the first stage 1 into segments having the fixed number of bits, with stuffing bits where needed. To each segment there is added a local header indicative of the router output line destination of the segment and each  
5 segment is stored in a buffer for onward transmission when a path towards that output line becomes available in the core switch.

The third stage 15 receives data over lines 11-14  
10 from the core switch, and holds the data until a complete packet is available. Then it reassembles the packet and stores the packets until the appropriate one of the output lines 16-19 is available to output data. The stored information in the first stage 1 is termed an input queue  
15 and the stored information in the third stage 15 is termed an output queue.

In this example, the core switch 10 operates to interconnect its input lines 6-9 with its output lines 11-  
20 14 according to control exerted by the control unit 20.

Assuming that all of the lines have the same capacity for carrying information then the switch shown in Figure 1 has no speed-up, i.e. lines 6-9 cannot remove information  
25 from the totality of the input queues stored in the buffers of the first stage 1 any faster than that information is provided to the input lines 2-5. In other examples there are more lines between the first stage 1 and the core switch 10 and the core switch 10 and the  
30 third stage 15 than there are input and output lines. Such embodiments provide spatial speed-up so that packet data can be removed from the input queues more rapidly

than the packet data is applied. It would alternatively be possible to provide temporal speed-up, or a wavelength division multiplex.

5 Continuing to refer to Figure 1, the control device  
20 monitors the size of the input and output queues and reconfigures the interconnections of the core switch in some defined way in response to those queues. In another embodiment, the interconnections of the core switch change  
10 either cyclically or according to the statistical conditions of the traffic in the network, and the control device sends packets to the core switch when a desired path is provided.

15 In the context of a MAN the network as a whole also has a network controller which manages the information flow within the network typically to avoid hotspots as far as possible. The network controller is remote from the routers that make up the network and thus is capable only  
20 of management rather than control at the individual packet or stream level.

Figure 2 shows the part of the input stage 1 of  
~~Figure 1 which is connected to input line 2, together with~~  
25 a part of the core switch 10 of Figure 1. Similar connectivity is provided for each of the other input lines 3-5.

Referring now to Figure 2, the input line 2 connects  
30 to header reading circuitry 30 of the input stage 1, which reads the header information from incoming packets on the line 2. In the context of a MAN, this header information

is MAN address data, not the IP address. After reading, this header data remains in the packet as part of the packet payload. The packet is passed through the header reading circuitry 30 to a segmenting circuit 32 which  
5 includes a serial-to-parallel converter stage that outputs bit-parallel data of standard width towards a dual-port memory 33. The extracted header information is fed to local header circuitry 31, which has a look-up table storing local headers indexed by packet address, and which  
10 provides an output to the memory 33. The output is a local header indicative of the output port of the router to which the packet is destined. Assuming a memory width of 128 bits the segmenting circuitry 32 might for example provide a bit-parallel output of 120 bits and the local  
15 header circuitry 31 provides 8 bits, the 8 bits being maintained identical for each of the segments of the packet and stored with each of those segments in the memory.

20 The second port of the memory 33 is a read output and is connected to line 6 of the core switch. This in turn is coupled to a selector 34 under control of the control circuit 20. The outputs of the selector 34 are connected to four VCSELs 40-43.

25

As noted above each of the inputs 2-5 has associated header reading circuitry 30, local header circuitry 31, and segmenting circuitry 32 as shown in Figure 2. It is possible to provide one memory 33 for each input 2-5 and  
30 this avoids memory bus contention. It may alternatively be desirable to provide fewer memories than this by the process of "sectorising" the inputs to the memory 33. In

the device later described with respect to Figure 4 each sector has four inputs and each sector has a single memory.

5       Sectorising has the further advantage that the flexibility of the device is improved, as follows. Each input sector has more than one output, all accessible from any packet in the input sector's common memory and each output sector has more than one input which can access the  
10   output sector's common memory. The paths through the coupling device are not dedicated to particular output nodes as they are in a non-sectorised device, as the coupling device only needs to provide a path between one of the input sector's outputs and one of the output  
15   sector's inputs for packets to be transferred to the output sector's common memory. The output sector's common memory then acts as a common memory switch and is accessed at a read port by a selector to connect the packet data to the desired output node of the sector.

20

The device shown in Figure 2 is non-sectorised and thus the memory 33 is connected only to input 2, and further memories are provided for each other input. These memories have outputs to the selector 34 similar to line

25   6.

Referring again to Figure 2, the line 6 from the memory 33 to the selector 34 is capable of carrying bit-serial outputs from the memory 33. Each bit-serial output  
30   is routed by the selector to a respective VCSEL 40-43...  
The controller 20 is aware of the present flow of information within the system and the state of the queues

in the memory 33 and operates the selector 34 in some predefined way, for example to minimise overall queuing time. The segments of each packet are supplied to a respective VCSEL so that an entire packet is output to a single VCSEL. In one embodiment the contents of an entire queue, which may contain several packets, are supplied to the VCSEL for transfer through to the core switch.

Referring now to Figure 3 which shows a part of the core switch 10 of Figure 1 and the output stage 15 of Figure 1, with an exemplary VCSEL 43 outputting light 46. It will be understood that in practice all VCSELs are likely to be operating simultaneously. In the figurative representation of Figure 3 the light is shown as having four different directions representing "fan-out". Fan-out may be achieved in a number of ways known to those skilled in the art, for example by lenses, by lenses and holographic gratings or by holographic gratings alone. Also it is possible to use optical fibres to provide fan-out. It is however preferred to use free-space fan-out as this is less complex and less costly.

The light is incident on a path controlling device 50 which here is a multiple shutter device for example a ferroelectric liquid crystal shutter matrix. Continued inspection of Figure 3 shows that the shutter device is divided up into four sections 51-54 and that each section of the shutter comprises four individual shutters 55-58. The number of shutters per section corresponds to the number of VCSELs and the number of sections corresponds to the number of inputs or input sectors. Each VCSEL is incident on a respective one shutter in each section, by

virtue of the fan-out optics and for ease of explanation the VCSEL 43 is shown as linked to the first shutter in each section. In each section 51 therefore the light from VCSEL 43 is incident upon shutter 55. The remaining  
5 shutters 56, 57 and 58 receive light from the other VCSELs 40, 41 and 43.

As noted above the physical arrangement of the shutters is not as shown diagrammatically. The VCSEL 43  
10 may for example provide a beam onto a rectangular array of shutters, the beam being incident upon four adjacent shutters with each other of the VCSELs 40-42, 44 and 45 being incident upon a different four shutters from the array.

15

Each shutter section 51-54 is connected via fan-in optics 61 to a respective one of four photodiodes, 63a-d. The photodiodes 63a-d detect incoming light, convert it into an electrical signal and apply it to the serial input  
20 of a respective serial-to-parallel converter 64a-d which have bit-parallel outputs connected to a write port of a respective dual-port buffer 65a-d. The read port 67 of each buffer 65a-d is connected via a respective parallel bus 67a-d to processing circuitry 66a-d whose outputs 16-  
25 19 form outputs of the router.

The control circuit 20 is connected to the shutter array 50 so that only one shutter per section is opened. In the present case shutter 55 of section 51 is opened and  
30 the remainder are closed.

Operation of the device of Figures 1, 2 and 3 will now be described.

As previously noted an input packet at input 2 is  
5 stored in memory 33 in the form of segments, each segment  
having an added local header indicative of the final  
destination port of the router - here node 16. The memory  
will also contain further packets held as segments with  
local headers indicative of other output ports.  
10 Information such as the length of the queue and the time  
of arrival of the earliest packet is provided from the  
memory to the control circuit 20. The control circuit 20  
also contains similar information concerning the queues in  
the memories from the other inputs 3-5. Furthermore the  
15 control circuit also contains information about the  
present state of the shutter array 50 and by virtue of  
this information is aware of which of the VCSELs 40-43 is  
currently transferring information to the photodiode 63a.  
As shown in Figure 3, the control circuit 20 is further  
20 aware of the state of the queues in the output buffers  
65a-d. It is however possible to dispense with this  
information at the local level as will later be described  
herein.

25 On the basis of some queuing strategy the control  
circuit 20 routes information from the memories in the  
input circuitry 1 to the selector 34 and thence to the  
VCSELs 40-43. In one arrangement packets are taken from  
each memory during every time slot so that selector 34  
30 will always take packets from each of the memories and  
route the packets of each memory to a respective single  
VCSEL.

It must be borne in mind that contention may occur in that at the time the subject information stored in memory 33 requires to be transmitted to photodiode 63a the  
5 photodiode 63a is already receiving information from another VCSEL. The control circuit 20 will be aware of the current state of the shutters which indicates which of the VCSELs, if any, is transmitting to diode 63 and will take the necessary action. This action may be retaining  
10 the information in the queue and instead transferring other information from memory for which there is a path available.

In the presently described example there are four  
15 inputs to the device and there are four paths within the core switch 10. It will however be recalled that it is possible to provide further paths within the core switch so as to provide spatial speed-up. This will be described later herein with respect to Figure 4.

20

In the present case, by way of an example it is assumed that VCSELs 40-42 are involved in carrying packets towards the outputs 17-19. This means that one of the  
shutters of section 52 is enabled, one of the shutters of  
25 section 53 is enabled and one of the shutters of section 54 is enabled. As at the present time no information is being carried towards output 16 all of the shutters 55-58 of section 51 are dark whereby no light reaches the photodiodes 63a. The control circuit has stored  
30 information which consists of a map showing that when VCSEL 43 is to carry information towards output 16, then shutter 55 of section 51 is to be opened to transmit

light. The control circuit also maintains dark shutters  
55 of sections 52-54 so that the light incident from the  
VCSEL 43 on those shutters cannot reach inappropriate  
outputs. It should be borne in mind that under certain  
5 circumstances it may be desirable for a VCSEL to provide  
light to more than one output for multicast or broadcast  
purposes and in this case the control will be implemented  
accordingly.

10 Light passes through the shutter 55 of the first  
section 51 and is output as light 46a. This is guided by  
the fan-in optics to the photodiode 63a as a time series  
of pulses and these are passed to the serial input of the  
serial-to-parallel converter 64a. The bit-parallel  
15 outputs of the converter 64a are applied to the write  
input of the buffer 65a until a complete packet has been  
received. The packet information is then fed out over  
read bar 67 to the processing circuitry 66a which de-  
segments the packet information and removes the local  
20 header data before outputting over the line at terminal  
16. The processing circuit 66a may if required queue the  
packet.

Referring now to Figure 4 an example of a non-  
25 sectorised router will be described in which the core  
switch 10 has spatial speed-up. Referring to Figure 4,  
the four inputs 2-5 each feed respective circuitry 120-3  
having the function of circuitry 30-3 of Figure 2,  
including the queue store. The output of circuitry 120-2  
30 feeds respective selectors 134-7. Each selector 134-7 has  
two outputs. Each output is connected to a respective  
VCSEL 140-7. The VCSELs are disposed to provide light onto

a shutter device 150 via fan-out optics. The shutter device has 4 sections, 151-4, and each section has two groups of four shutters, 160-3, 164-7. The fan-out optics here provides free-space paths, and consists of lenses. In  
5 other embodiments, gratings or combinations of gratings and lenses are used. The free-space paths are such that light from each VCSEL is incident on a respective predetermined one shutter of each shutter section.

10 On the other side of the shutter device 150 fan-in optics fans-in light from each shutter section to two optoelectronic diodes, such that light from each group of four shutters is guided to a respective diode from eight such diodes 260-267. Each diode has a respective shift  
15 register 270-277 connected at its data input to receive the serial data output of the diode, and each shift register has taps for bit-parallel read-out of the data, the bit-parallel data being fed to a respective buffer store 280-287. The buffer stores 280-287 are shown as  
20 connected in pairs to four circuits 290-293, each including output queuing circuitry and each connected to a respective output line 16-9.

---

25 The control circuit 20 is connected to the input circuit 1 and to the shutter device 150. The control connection from the control circuit 20 to the shutter matrix 150 may make use of an additional VCSEL, to avoid the need for wiring.

30 In use, consider input packet data at input line 2, which is to be sent to a destination accessible from output line 16. The packet data has an IP address header

as part of its payload, and a network address. The circuitry 120 accesses the network address, and by consulting a routing table which may be in the circuitry 120 itself or in the control circuit 20, a local header is  
5 derived indicative of output line 16. The circuitry 120 then segments the packet data and queues it in buffers.

The control circuit 20 checks the state of the shutter device 150, and checks whether VCSELS 140 and 141,  
10 both accessible from circuitry 120, are both occupied. If so, the packet data remains queued. Equally if the shutter state and emission state of other VCSELS indicates that the paths to the diodes 260, 261 are blocked by other traffic, the packet data remains queued.

15

Once the two conditions are satisfied of an available VCSEL and an available path, the queued data is selected by the selector and sent to the free one of the VCSELS 140,141. The shutter appropriate to the VCSEL for use in  
20 the shutter section 151 is then opened and the data sent across the core switch as a serial stream. In this case all data in the queue are sent. If the diode 260 is set to receive the stream, the data arrive at shift register 270 and are de-serialised before storage in buffer 280.  
25 Once a whole packet is available, the local header data may be removed from the segments of that packet and the reconstituted packet transferred to the store 290 into an output queue.

30 It should be noted that the presence of speed-up allows data to leave the input queue faster than it

arrives there. It also allows greater flexibility and greater freedom from blocking.

As in the present embodiment the whole queue for a particular output line is emptied through a single connection of the core switch, it is not possible for both VCSELS 140, 141 to be sending information directly to the same output line 16 although two packets could be sent via 507 with one direct and the other queued in 281 or 282. In embodiments where packets are sent individually, it would be possible for both VCSELS to carry data for the same destination, but measures would have to be taken to ensure that packets leaving the router for the same end destination leave the router in the order received.

15

Referring now to Figure 5 a single sector 501 of a sectorised router is shown. Each sector has four inputs 502-505 and four outputs 516-519. Each sector consists of an input stage 506, a core switch stage 507 and an output stage 508. The input stage 506 and the output stage 508 consist generally of common memory switches having, in the case of the input stage four inputs and six outputs and, in the case of the output stage, six inputs and four

---

20 outputs. The common memory switches each include an input

25 demultiplexer having a bit-parallel output which is connected to the write bus of a dual-port memory, whose second port is connected to a multiplexer providing the stage output. In the case of the input stage 506 a demultiplexer 520 receives the four inputs 502-505 as its 30 inputs and provides a bit-parallel output on a bus 521. The bit-parallel output is provided to a block 522 which contains header translation circuitry, segmenting

circuitry and a memory as previously discussed with respect to earlier figures. The memory read bus 523 forms the input to a multiplexer 524 which has six outputs 525-530. Each of the output lines goes to a respective one of six VCSELs 531-6. The VCSELs are connected by fan-out optics to a shutter unit 537. The present router has six input and output sectors and to provide the necessary connectivity together with a speed-up of 1.5 (due to there being six VCSELs per four inputs) the shutter unit 537 has six groups of six shutters per sector. In Figure 5 the first group of shutters is shown as 538-543 and the first shutter of the second group is shown as 544. For a 24x24 switch there will accordingly be 216 individual shutters. The first VCSEL 531 is connected via the fan-out optics to the shutter 538 of the first group and to no other shutters in the sector. It is however connected via the fan-out optics to one shutter of one group of each of the other sectors as well. The second VCSEL 532 is connected to the first shutter 544 of the second group of shutters in the sector shown in Figure 5 but is connected via the fan-out optics to no other shutter in the sector shown although it is also connected to one shutter in each of the other sectors, a different shutter to that to which VCSEL 531 is connected. The second shutter 539 is illuminated by a VCSEL in the second sector, the third shutter 540 being illuminated by a VCSEL in the third sector and so on. Any light which is passed by the first group of shutters 538-543 is collected by fan-in optics onto an opto-electronic diode 545 of six such diodes 545-550. Each of the diodes 545-550 provides an input to a respective circuit block 551-556. The circuit blocks 551-556 are substantially identical and hence only block 551

will be described. The block 551 has a shift register 557 having a serial input and plural taps, the serial input being connected to the respective diode 545 and the plural taps being connected to a buffer 558. The buffer has a  
5 bit-parallel output 559 which forms an input to the output stage 508. The output stage 508 has a six-input demultiplexer 560 which has a bit-parallel output 561 to a circuit block 562 which includes de-segmenting circuitry and a dual-port memory. The dual-port memory has a read-  
10 port 563 which is connected to a multiplexer 564 having the four bit-serial outputs 516-519.

Operation of the device shown in Figure 5 will now be described:-

15

Packet data input on lines 502-505 are demultiplexed on to the bit-parallel line 521 and the resulting bit-parallel data is applied to header translation circuitry before segmenting and storage in the input queue memory  
20 with each segment having a local header provided by the header translation circuitry. The output port 523 is bit-serial and is connected by the multiplexer 524 to an available one of the six VCSELS 531-536. By "available"  

---

it is meant that the VCSEL is not already being used to  
25 transfer data, and that a path through the shutter is available to the sector containing the output port required. To explain this more fully, it may be that the VCSEL 531 is available to transfer data whereas all remaining VCSELS 532-536 are already occupied. If however  
30 the shutter group 538-543 is already engaged in transferring data to the photo-sensing diode 545 then there is no path available from the VCSEL 531 which could

reach the required output line 516. In this case the data for transfer to the line 516 is retained in the queue store.

5        If however there is available a VCSEL for transfer to the output stage 508 and if there is available a shutter having a path from the VCSEL to one of the photo-sensing diodes 545-550 then the information is routed to that VCSEL and a routing is set up and fixed until the entire  
10    content of the queue is passed across the optical link. In the present case the queues are organised by output port. It would of course be possible to order the queues by output sector and to carry out the sorting between the output ports in the output stage but this would result in  
15    additional complexity if there was a need to maintain packets in the order of their arrival.

      Assuming that VCSEL 531 is used to transfer data destined for output port 516, then this data is output in  
20    serial form from VCSEL 531 to the shutter 538 and similarly to a shutter of each of the other sectors. If the data is only for the output 516 then the remaining shutters receiving the light from VCSEL 531 are maintained closed and only shutter 538 is made transparent. In any  
25    event, all of the remaining shutters 539-543 of the first group are made opaque so that the only light received by the photo-sensing diode 545 comes from the VCSEL 531. The serial data from the photo-sensing diode 545 passes into the shift register 557 which is self-clocked and when the  
30    shift register is full the data of a segment is transferred to the buffer store 558 and the shift register cleared. The remaining data of the packet stream from the

input queue is transferred in like fashion from the shift register into sequential memory locations of the buffer store 558. When the queue is empty, the data is output on the bit-parallel line 559 and picked up by the  
5 demultiplexer 560 being passed in bit-parallel form over bus 561 to the circuit block 562. The segments have their local header data removed by the circuit block 562 and the packets are reassembled in the output queue store. The reassembly typically takes the form of linking pointers  
10 between the different memory locations of the output queue store so that the end of each segment indexes the start of the next. The output queue store then passes data through the multiplexer 564 to the output line 516.

15 It will be seen from this description that control of the flow of packets across the core switch depends only upon knowledge of the input queue state and the available paths. It is not a requirement that information be signalled at the packet rate from the output stage 508.  
20 However of course the overall management of the router system takes into account the size of the queues in the output queue store to prevent hotspots from arising. It will be seen that the six VCSELs 531-536 are all capable  

---

of transferring information to the desired output sector  
25 and that there is no linkage between a VCSEL and any one output sector as in the case of the non-sectorised device.

Referring now to Figure 6 another example of a router will now be described. The router 208 has four input  
30 modules 210-213 of which input modules 210-212 each receive inputs from four input lines 231, 232, 233 and 234. Each of the input modules 210-213 has its own sector

memory so that packets from each of the three sets 231, 232, 233 of four input lines is carried via a respective write bus to the sector memory. The packets on the sets of input lines 231-233 carry network routing information in the form of headers. These headers are read within the sectors 210-212 and the packets are segmented as previously described with each segment having a pre-pended local header indicative of the destination mode within the router to which the packet is sent.

10

The fourth input module 213 has six inputs 234 from a passive optical network which extends from a preceding router. The packet information carried on the six inputs 234 consists of packet segments each carrying a pre-pended local header part indicative of a virtual destination within the input sector 213. The input sector 213 removes the local header information, examines the network header information contained within the packet and adds a new local header for the router 208 before queuing the segments in a sector memory.

20

Each of the input modules 210-213 has six VCSEL outputs and these are applied using fan-out optics 214 via free-space paths to a shutter module 209, the module having first to fourth shutter sectors 215-218. Each of the shutter sectors has twenty-four shutters and is operated by the control circuitry 235 so as to set only six of the twenty-four shutters to the "on" condition.

25

The output of the first shutter section 215 is fed via fan-in optics 219 to an output module 223 which receives the six inputs, stores these in a buffer and then

30

reassembles the segments before outputting to the required one of four output lines 227. Similarly the second shutter section 216 has fan-in optics 220 leading to an output module 224 which has four outputs 228. The third  
5 shutter section 217 also has fan-in optics 221 but instead of these leading to an output module there is instead an optical regenerator device 225 which receives the six input signals from free-space and launches those signals into a passive optical network, here an optical  
10 transmission link consisting of six optical fibres 229 for monomode transmission. In other embodiments the link consists of a single WDM fibre. The six fibres lead to an Internet termination which may be remote from the router 208. The Internet termination includes de-segmenting  
15 circuitry which reassembles the packets and removes the local header information before launching the output packets to the Internet.

The fourth shutter section 218 has fan-in optics 222  
20 which also leads to an optical regenerator 226 feeding the transmission link. The transmission link forming part of a passive optical network, lead to a second router which is remote from the router 208.

---

25 In much the same way as the input sector 213 of the router 208, the input sector of this remote router is able to combine the functions of the output stage of the router 208 and the input stage of the remote router. This is advantageous because the operation of the router 208 does  
30 not require knowledge of the status of the output stage of the router. The immediately-required information is confined only to the conditions of the input queue and the

shutters. Thus, the control circuitry 235 which is physically close to the router can operate with a rapid response time without the delays that would be incurred if information from a remote output stage were required to control packet flow. By combining together the input and output queues in the input module of the router 208 (and likewise the remote router) the number of queues in the network is reduced overall. This has the advantage of reducing memory requirements and also of reducing network delay.

There is also provided an overall management structure for the network. Typically, the management device will contain routing tables and will be connected to the routers to observe the packet flow - for example by checking queue status. The controller then can take account of locations where queue lengths are increasing so that internal traffic can take a less congested path through the network.

Queuing strategies will now be described for the situation where no path from one of the input module 211 is immediately available:

In one arrangement, the input queues are a function of destination port and a FIFO operation is used.

In another, service criteria are provided so that packets of given priority have a guaranteed performance through the network. Within these embodiments, higher priority packets are moved upwards towards the head of such queues by pointer manipulation. Where congestion

occurs, this is indicated by input or output queue overloading. Queue overloading is reported to the network management which calculates whether a different route through the MAN would remove the congestion.

5

If so, the routing tables in the relevant nodes of the MAN are changed to effect this, and the existing queues at the hot spot would be left to empty as soon as possible. Any fresh packets that would encounter the  
10 existing bottleneck would take the new path through the MAN. In some embodiments, the routers take precautions to prevent packets getting out of order by storing packets that should occur later but do in fact arrive earlier. In other embodiments, the receiving device instead performs  
15 this function.

In other arrangements, a weighted fair queuing algorithm is used to control the device.

20 In yet other arrangements, queue stores are a function of the destination sector.

In many router architectures, the speed-up is high -  
~~for example a cross-point device having N inputs and N~~  
25 output has a speed-up of N. The use of the present device with sectorisation and a high speed optical path, together with the use of general knockout allows speed-up to be typically of the order of 1.75 to 2.0, with an acceptable blocking performance. Providing extra paths can reduce  
30 blocking in the packet router device 208. When spatial speed-up is in effect some paths may also be fixed. The

ratio of fixed paths to switchable paths may typically be 2:1.

Alternatively and/or additionally to spatial speed-up, temporal speed-up may be provided. Temporal speed-up is where information is transmitted over a device output line at a higher rate than it is received at the input to the device.

Figure 7 shows a high-level block diagram of an embodiment of one sector of the input stage to the core switch of a sectorised router using a path-on-request technique for transport of packet data across the core switch. As has previously been noted, packets are segmented at least in part due to their arbitrary length. This first stage segmentation takes place upstream of Figure 7, as does network header reading and the addition into the first stage segments of local headers. Referring to Figure 7, packet segments 750 are serially input to a local header read device 800 and thereafter read into input buffers 801. The local header information is passed to the control device. The parallel output of the input buffers is then read into a common memory switch 802. There are time constraints on control processing and shutter latency which are eased if the input is held for a delay after the packet segment header is read and passed onto the control function. This means that the peak rate of packet arrival can be reduced to become nearer the mean rate. To allow for the delay, common memory switch 802 is split into two sections - a delay section with a delay equal to the required latency value and a queue section.

Output 751 from common memory switch 802 is transferred serially when appropriate through an output packet buffer 803 into a re-timing buffer circuit 804 for output to the VCSELs. The re-timing buffer circuit  
5 contains one re-timing buffer per VCSEL, and an embodiment of such a buffer is described later herein with respect to figure 8.

In other embodiments, electronic cross-connects or  
10 cross-points are used, but the arrangement using a common memory switch described above provides a preferred interface between the router and the core switch, as the internal queue reduces the requirement on the number of switch paths. Equally, the fact that delay can be readily  
15 included simplifies the design.

The input electronics further divides the segmented packet into a "tranche" of R words of length W, after adding the local header in front of the first word in each  
20 segment. Stuffing bits (SB) 614 are inserted locally between each word to give a total word length of  $W + SB$ . As far as the core switch is concerned it is dealing with tranches and needs to know nothing about how tranches are related to the input packets.

---

25

Figure 8 shows a block diagram of an example of a re-timing buffer, having a buffer store split into three buffers 610-12 each with a length  $0.5W$ , thus providing a total length  $1.5 W$ . A serial input 751 is commutated by a  
30 cyclic commutator 613 between the three buffers such that data is read into and out (by a second commutator 615) of them cyclically. Three, rather than two, buffer stores

each with a length  $0.5W$  corresponding to the time available for setting a shutter, are used because the insertion of stuffing bits requires read out to be faster than read in. The three buffer solution avoids the need to  
5 clock in and out at different rates simultaneously.

Each re-timing buffer is assigned a time slot modulo  $N1$ ,  $N1$  being given by  $N1 = N(1 + k)$ , where  $k$  is the speed-up of the switch. The input is sorted according to output  
10 sector. Because the fan-in at the input of the output stage of the switch causes data from all input sectors to be overlaid on each other, it is necessary to ensure that no two (or more) input sectors use the same numbered buffer to send to the same output sector. If for  
15 example buffer  $i$  of sector 1 is directed to sector 4, no other sector's  $i$  buffer is directed to sector 4. Thus an input on sector 2 directed to sector 4 uses another port,  $j$  say.

20 A control algorithm tells the input which output buffers are allocated and then informs the shutter plane which shutters to open.

A lower level block diagram of an implementation of  
25 the functional architecture of Figure 7 is shown in Figure 9. The implementation is split into three parts namely an input buffer part 801, a central part 802 and an output part 803. In the input part 803, input data 800 is transformed from serial to parallel format. The parallel  
30 data is transferred into the central section 802, which comprises a FIFO, where it is delayed to allow for the latency issue discussed above, and queued until output is

possible. In the output section the data is stored in a buffer termed an output packet buffer, prior to transfer into the re-timing buffer. Because of the time (latency) needed to set up the path due to the use of the optical  
5 shutters, the size of the centre section FIFO will depend on that latency. As the overall device allows speed-up to be kept small, for instance typically less than 3, the effect of a queue on the value of speed-up is not significant.

---

Input Sequence to input stage

1. Detect headers and store in the input packet assembly  
5 block 801.
2. Scan 805 header stores and transfer headers to  
address comparator/logic 806 where any necessary  
translation takes place. The address of the input packet  
10 is implicit in the time slot and a single bit denotes the  
position of the commutator.
3. Using read/write logic 812 write the next free  
address location of the FIFO store of the centre stage  
15 from a free address location store 811 into an input  
stream pointer store 807. Set a flag bit. In the relevant  
time slot, transfer the content of the input buffer to the  
delay section of the store 802 of the centre stage. Reset  
the flag bit.  
20
4. Ask control to set up the switch path and after the  
pre-set delay move the packet from the delay section to  
the queue section of the store 802 of the centre stage.
- 25 5. Write the address location of the store 802 of the  
centre stage, together with writing the destination stream  
address into an output stream pointer store 808. Using a  
pointer logic circuit 813, write a pointer to the output  
stream pointer store into an output stream pointer FIFO  
30 809.

Output Sequence from the input stage.

1. Scan periodically the output packet buffer 803 and  
5 when empty slots are found, set bits in a free-slot bit  
map 810. Translate the bit map settings into destination  
addresses and set bits in the destination bit map 810 .
2. Asynchronously scan the output stream pointer queues  
10 from the point where the last scan finished. On finding a  
queue with content, and if the relevant bit in the  
destination bit map is set, set a bit in an output stream  
pointer store 808 and pop the output stream pointer FIFO  
809. The destination address in the output stream packet  
15 store is replaced by the output packet buffer address. In  
the relevant time slot a transfer is made between the  
store 802 of the centre section into the output packet  
buffer 803 and the output stream pointer is returned to  
the output store pointer FIFO 809.

20

The time slot intervals ( $t$ ) for the store of the  
centre section are proportional to the fan-out, the number  
of words per segment, and the store width in bits, and  
~~inversely proportional to the number of input streams and~~  
25 the bit rate in bits/sec.

In embodiments where increase of the time slot  
duration is required, the main store is split into  
sections for access.

30

Figure 10 shows a block schematic diagram of an  
embodiment of the output stage electronics. After

conversion from serial optical to serial electronic streams by photodetectors, e.g. optoelectronic diodes, the serial data are stored in shift registers 901 where the local destination headers can be read. The outputs of the shift registers 901 are read out in parallel on a bus 902 of width W into a packet store memory 903, a dual port SRAM, (which acts as an intra-sector switch) where they are queued until their destination port is free. The larger W, the easier are the requirements on bus speed and memory write time.

The rate S at which the shift registers need to be addressed is:  $S = B n/W$  times/s where B is the input bit rate and n is the number of inputs to each sector.

#### Input Sequence to output stage

1. Detect local header

2. Having detected local header, start a word count and when the address field is found staticise it.

3. Allot two time slots, modulo N or n', in the write cycle of the packet store memory 903.

4. In the first slot of the first word of a tranche, read out the address field to a central controller 904.

In the central controller, compare the most significant bits of it with the own sector address, and return 1 for me, 0 not for me.

If 0 no further action is taken on this stream and the contents of the shift register are shifted out and lost.

5 If 1 store the least significant address bits (LSB), indicating the output port number (OPN), in an incoming stream buffer for the stream, which buffer also has a tranche counter.

Set the tranche counter to R-1.

10 Take the starting address of the packet store, where incoming data is to be stored as a block, from an incoming address location FIFO holding the incoming address locations.

Store the starting address in the incoming stream buffer.

15 If the incoming address location FIFO is empty (indicating queue overflow) discard the packet data and inform central control.

5. For all values of R, in the second modulo N or  $n'$  slot, examine the relevant input stream buffer to determine whether the stream is active or not.

If the stream is active, take the store address from it and load into the write address buffer of the packet store memory.

25 Connect the contents of the relevant shift register which is in the idle phase (i.e. not shifting) at this time, to the packet store write bus to transfer the contents to the packet store. (It is possible to set the shift register to idle because of the stuffing bits at the front of the words additional to the first word in each tranche.)

30

Decrement the tranche counter in the incoming stream buffer.

If the tranche count is zero, set the incoming stream buffer to idle.

5

6. On the transfer of the first tranche to the packet store, use the LSB from the incoming stream buffer to address an output stream pointer FIFO holding the relevant output stream pointer, place the packet store address is placed there. As one bit of the LSB indicates a multiple address, where this bit is set a translation is required and addresses are placed in several output stream pointer FIFOs

15 B Output Sequence.

Asynchronous Part

1. Scan output stream buffers 905. When an idle one is found, scan the output stream pointer queue from where the last scan finished. On finding a queue with content, perform the following on the stream output buffer:

20       set state to 'active',  
         transfer store pointer from stream pointer FIFO,  
         load FIFO number (i.e. output port number OPN),  
25       set tranche count,  
         set bit count  
         set 'ready bit'.

Synchronous Part.

30 2. Each output stream buffer is allocated a fixed time slot modulo OPN and the scan cycle time T has an integer

relationship such that  $T = WB/I$  where  $T$  is an integer,  $I$  is an integer ( $I \geq 1$ ) and  $B$  is the bit rate.

Examine the stream buffers in their time slot.

If ready, transfer the address of the output stream  
5 data to the read address buffer of the packet store and  
read the packet store content read into the output buffer  
905 ready for parallel to serial transformation. Reset the  
ready flag, increment the tranche count and start counting  
word-bits.

10 When the bit count reaches zero, set the ready flag  
and transfer the next tranche.

3. While the transfer takes place between the packet  
store and output buffer, insert idle bits in the serial  
15 stream.

4. When the tranche count reaches zero and the last word  
is transferred, return the store pointer the address FIFO.

20 In some embodiments, sequences of control actions are  
pipelined rather than attempting to perform all the  
actions of a sequence in one packet store cycle.

---

25 The above discussion of Figures 7-9 only constitutes  
one illustrative example of the possible control method  
and implementation.

A controller (e.g. a microprocessor) is also provided  
to initialise the system for example loading own-sector  
30 addresses and FIFO addresses, to synchronise it and to  
accept fault reports. A system reset is provided and  
start- synchronising pulse for the scanners.

### Metropolitan Area Networks

Referring now to Figure 11, an example of a Metropolitan Area Network 910 has three external  
5 connections 912-914 to the Internet, these three connections being made to three nodes 915-917 of the MAN.

The MAN also has seven internal nodes 918-924. The internal nodes 918-924 and the external nodes 915-917 are  
10 shown connected by an exemplary network of transmission links 925-939.

As is known in the art, the external nodes 915-917 contain full Internet routing tables, and allow  
15 translation of Internet addresses into an abbreviated address format which is internal to the MAN.

The MAN also has a network control device 911 which has by directional connections 940 to all of the nodes of  
20 MAN. The network control 911 performs a number of functions, including which is the function of loading and updating routing tables in the internal nodes as a result of monitoring the state of MAN as a whole with a view to reducing or removing the occurrence of traffic bottle  
25 necks. By way of example, if information comes in at external link 912 with a destination address indicative of internal node 923 then routing can occur via link 925 or 927 at the external node 915. Clearly there are a number of paths within the MAN that lead to the destination node  
30 923 so that, for example, at a particular point in time, the routing table at node 915 may be set to route traffic to node 923 via links 925, 929 and 937. If however a

bottle neck occurs at link 931 for example due to traffic from node 919 to node 922 then the routing tables may be amended so as instead to route via links 925, 928 and 936. As known to those skilled in the art, various perimeters  
5 may be used to detect when the routing tables require updating.

Turning now to Figure 12, this shows how a passive cross connect, for example, a passive optical network 949  
10 can be used with a MAN 950 to connect nodes of the MAN to each other and to route external to the MAN, for example to the Internet. Figure 12a shows a part of the MAN 950 having one external node 951 with a minor trunk 956. Two internal nodes 952 and 953 are shown. 958 and 959  
15 represent the trunk inputs to node 952 and 953 respectively. There are two major trunks 954 and 955 connected to routes external to MAN. The node 951 is connected to a four nodes 961.

20 The cross connect 949 is expended in Figure 12b to show how connections are organised in more detail. Each of the three routers 951-953 is split into output sections 951a-953a and input sections 951b-953b. These sections are jointed by optical interconnect as previous described.

25 Each of the routers has three sectors with two inputs and two outputs per sector. The number of connections between input and output, with speedup, is three per sector pair. On the input side of the trunks 954a and 955a, in coming packs are reformatted at blocks of 961 and 962 to conform  
30 to the internal address structure of the MAN. The reformatted packs are input to the nodes 952b and 953b via lines 958 and 959. The trunk outputs come from 952a and

953a via 958 and 959 to the electronic output modules 963 and 964. There the packet data is queued as necessary and then output via 965 and 966 in the external network format to the trunk connections 955b and 955c. The electronic  
5 output modules 963 and 964 operate similarly to the electronic output modules in Figure 6.

Embodiments of the present invention have been described with particular reference to the examples  
10 illustrated. However, it will be appreciated that variations and modifications may be made to the examples described within the scope of the present invention.

CLAIMS

1. A packet router comprising an input stage, an output stage and a coupling stage for coupling the input and  
5 output stages,  
the input stage having plural input devices each for receiving packets having packet data comprising packet destination data, each input device having at least one output element;  
10 the output stage having plural output devices defining plural router output nodes, each output device having at least one input element;  
the coupling stage providing paths for signals between said output elements of the input devices and said  
15 input elements of the output devices;  
wherein each input device has circuitry arranged to respond to packet destination data of a packet received by said input device for adding, to the packet data of the packet, information indicative of a router output node at  
20 which the packet is to be output;  
wherein the router further comprises a control device connected to said input stage and to said coupling stage for causing packets to be output to said coupling stage in dependence on said information;  
25 wherein each output device has circuitry for removing said information prior to output of packets; and  
wherein the router further comprises a connecting device arranged to receive said signals from paths of the coupling stage and to transfer said signals to a further  
30 said output device disposed remote from said input stage.

2. A packet router according to Claim 1, wherein each  
said input device has a plurality of inputs, a plurality  
of output elements, and comprises a respective memory  
arranged to receive data from all of the said plurality of  
5 inputs and arranged to output data to all of  
said plurality of output elements; and wherein each output  
device has a plurality of input elements and a plurality  
of router output nodes, and comprises a respective memory  
arranged to receive data from all of the said plurality of  
10 input elements and arranged to output data to all of said  
plurality of output nodes.

3. A packet router according to Claim 1 or 2, wherein  
said coupling stage is arranged to vary the paths between  
15 the input stage and the output stage, and said control  
device is arranged to cause packets to issue from the  
input stage when a desired path is provided.

4. A packet router according to Claim 1 or 2, wherein  
20 said control device is arranged to control the coupling  
stage to set up a desired path from the input stage to the  
output stage and to cause packets to issue from the input  
stage for the desired path.

25 5. A packet router according to any preceding claim,  
wherein the coupling stage is arranged to provide at least  
one fixed path.

6. A packet router according to any preceding claim,  
30 wherein the input devices comprise segmenting circuitry  
arranged to divide received packets into segments of  
common length prior to application to said coupling stage,

wherein each segment includes the said router output node information of the packet and the output devices comprise desegmenting circuitry arranged to assemble segments received from said coupling stage into packets.

5

7. A packet router according to any preceding claim, wherein the input devices have optical output elements and the output devices have optical input elements and the coupling stage is arranged to provide free-space optical  
10 paths between said optical output elements and optical input elements.

8. A packet router according to any preceding claim wherein the connecting device comprises a passive optical  
15 network.

9. A packet router according to Claim 7 or 8, wherein the input stage has a plurality of inputs capable of carrying a first plurality of packets to said router in a  
20 given time period, and the coupling stage is capable of providing said paths between said output elements of the input devices and said input elements of the output devices, wherein said paths are arranged to be able to  
~~carry more than said first plurality of packets in said~~  
25 given time.

10. A packet router according to Claim 9, wherein the number of spatially separate paths provided by said coupling stage is greater than the number of inputs to  
30 said input stage.

11. A network comprising a packet router according to any preceding claim wherein each input device comprises storage for holding queues of packet data prior to issue to said coupling stage, and each output device has storage  
5 for queues of packet data received from the coupling stage, and further comprising at least a second packet router, the said at least a second packet router having a second router input stage, a second router output stage and a second router coupling stage for coupling the second  
10 router input and output stages, wherein the second router input stage has plural input devices each for receiving packets having packet data comprising packet destination data, each second router input device having at least one output element and storage for holding queues of packet  
15 data prior to issue to said second router coupling stage, wherein the second router output stage has plural output devices defining plural output nodes, each output device having at least one input element, wherein the second router coupling stage is arranged to provide paths between  
20 said output elements of the input devices and said input elements of the output devices, and wherein at least one of the input devices of the second router input stage is provided by said further said output device of said packet router disposed remote from said input stage of said first  
25 packet router, wherein each queue of packet data received from the coupling stage of the first packet router forms a queue of packet data for issue to the coupling stage of the second router.
- 30 12. A network comprising a first and at least one second packet router, each packet router comprising an input stage having plural input devices, an output stage having

plural output devices and a coupling stage for providing paths between said input devices and said output devices; each input device having storage for holding queues of packet data prior to issue to said coupling stage, each  
5 output device having storage for queues of packet data received from the coupling stage;

wherein at least one of the input devices of the second packet router is provided by an output device of said first packet router such that each said queue of  
10 packet data received from the coupling stage of the first packet router forms a queue of packet data prior to issue to said coupling stage of said second router.

13. A network according to Claim 12, wherein each said  
15 input device has a plurality of inputs and a plurality of output elements and a respective memory providing said storage for holding queues of packet data prior to issue to said coupling stage arranged to receive data from all of the said plurality of inputs and arranged to output  
20 data to all of said plurality of output elements, and wherein each output device has a plurality of input elements and a plurality of router output nodes and a respective memory providing said storage for queues of  
packet data received from the coupling stage and arranged  
25 to receive data from all of the said plurality of input elements and arranged to output data to all of said plurality of output nodes.

14. A network according to Claim 12 or 13, wherein each  
30 packet router has a respective control device connected to its input stage and to its coupling stage for outputting

packets to said coupling stage in dependence on routing information carried by packets.

15. A network according to Claim 14, further comprising a  
5 management device connected to receive information on the size of queues in each said output device.

16. A network according to Claim 15 wherein the  
management device is connected to each control device for  
10 modifying routing tables in accordance with said queue size information.

17. A network according to any of Claims 12-16, having  
means for discarding packets in said output stages if  
15 queues therein overflow.

18. A network according to any of Claims 12-17 wherein  
the coupling stage of at least the first packet router is  
arranged to optically couple the input stage of the first  
20 packet router to the output stage of the first router.

19. A network according to Claim 18, wherein the said  
coupling stage is arranged to provide free-space  
connections.

25

20. A method of routing packets using a packet router  
comprising an input stage, plural output devices and a  
coupling stage for coupling the input stage and output  
devices, wherein at least one of the output devices is  
30 spatially remote from the coupling stage;

the method comprising:-

in said input stage, examining packet destination data of a packet received by said input stage and in response thereto

5 adding, to the packet, router information indicative of a router output node of said at least one of said output devices, at which the packet is to be output to provide enhanced packet data;

10 in dependence on said router information, determining whether a path is available from an input of said coupling stage to an output connected to said at least one output device;

15 outputting said enhanced packet data to said input of said coupling stage, whereby the enhanced packet data is carried to an output of said coupling stage for said at least one output device having the said router node;

receiving the enhanced packet data from said coupling stage output and transferring the packet data over a link to said at least one output device;

20 receiving said enhanced packet data in the said output device;

removing said router information; and

outputting said packet at said router output node.

---

25 21. A method of routing packets using a router comprising an input stage having plural output elements, plural output devices each having plural input elements, the plural output devices each having a plurality of output nodes, said output nodes together defining the output  
30 nodes of said router, and a coupling stage for coupling the plural output elements of the input stage to plural coupling stage outputs, wherein at least one output device

is spatially remote from the coupling stage and the router further comprises a link between predetermined outputs of said coupling stage and the plural inputs of said at least one output device;

5       the method comprising:-

receiving respective packets at each of plural inputs of said input stage;

in response to packet destination data of said packets, adding to each packet respective router node  
10 information indicative of a router output node at which the said packet is to be output, thereby to form enhanced packet data comprising said packet data and said router node information;

storing said enhanced packet data for each packet in  
15 a common input memory;

in dependence on said router node information indicative of an output node in said at least one output device, determining an available path through said coupling stage from an output element of said input stage  
20 to one of said predetermined outputs of said coupling stage;

outputting said enhanced packet data from said common input memory to said output element, whereby the enhanced packet data is carried to one of said predetermined  
25 outputs of said coupling stage;

transferring the enhanced packet data over said link to one of said plural inputs of said at least one output device;

receiving said enhanced packet data at the said  
30 output device;

removing said router node information indicative of said output node to form packet data;

storing said packet data in a memory common to the input elements of said output device and to the output nodes of said output device; and

outputting a packet at said router output node from  
5 said memory.

22. A method according to Claim 20 or 21, comprising varying paths provided by said coupling stage between the input stage and the output stage, and causing packets to  
10 issue from the input stage when a desired path is provided.

23. A method according to Claim 22, wherein said varying step comprises providing a sequence of path combinations,  
15 and selecting between said path combinations on a timed basis.

24. A method according to Claim 22, wherein said varying step comprises providing a set of path combinations, and  
20 selecting between the members of said set in accordance with a statistical analysis of traffic in said router.

25. A method according to Claim 22, comprising  

---

controlling the coupling stage to set up a desired path  
25 from the input stage to the output stage and issuing packets from the input stage to the desired path.

26. A method according to Claim 22, wherein the coupling stage is arranged to provide at least one fixed path.

30

27. A method according to any of Claims 22-26, comprising dividing received packets into segments of common length

prior to application to said coupling stage, and adding the said router node information to each segment.

28. A method according to any of Claims 22-27, comprising  
5 coupling between the input stage and the output devices using free-space optical paths.

29. A method according to Claim 28, wherein transferring step is carried out using a passive optical network.

10

30. A method according to any of Claims 22-29, comprising carrying data across said coupling stage faster than said data is received at said input stage.

15 31. A method according to any of Claims 22-30, comprising providing a number of spatially separate paths in said coupling stage wherein said number is greater than a number of inputs to said input stage.

20 32. A method according to any of Claims 22-31, comprising:

holding queues of enhanced packet data prior to issue to said coupling stage,

25 holding queues of packet data received from the coupling stage,

30 locating at least one of said queues of packet data received from the coupling stage at an input of a second router having a second router coupling stage, said second router holding queues of packet data prior to issue to said second router coupling stage, and using said at least one of said queues as a said queue of packet data prior to issue to said second router coupling stage.

33. A method according to any of Claims 22-32, comprising  
providing information on the size of queues of data  
received from said coupling stage, and using said  
5 information to effect changes on routing information.
